May 2011

Abstract - This paper proposes a Bayesian approach to estimate a factor augmented productivity equation. We exploit the panel dimension of our data and distinguish individual-specific and time-specific factors. On the basis of 14 technology and infrastructure indicators from 37 countries over a 10-year period (1998 to 2007), we construct summary indicators of these two components and estimate their effect on the growth and the international differences in GDP per capita.

Keywords: Bayesian factor-augmented model, innovation, MCMC, panel data, productivity.

JEL classification: C23, C38, O47

1 Introduction

Why growth rates differ, what explains differences in productivity and what are the conditions for economic development, those are fundamental questions that continue to preoccupy economists. Besides the traditional inputs - labor, capital, energy and other intermediate inputs - technology, infrastructure and institutions are some of the variables that are often advanced to explain the evolution and the country gaps in productivity. How exactly those explanatory variables affect the total factor productivity residual requires some structural, multi-equation, modeling. This is not the purpose of this paper. Our goal in this paper is to try and ascertain the importance of these “explanations” of the residual on the basis of a certain number of indicators that supposedly capture those broad explanations. To take the example of innovation, instead of including separately measures such as R&D, the number of new products, the number of patent applications or grants, the number of trademark applications, the number of publications, ... could we not create some kind of index of innovation on the basis of which we could compare the performance and the contribution to productivity in different countries?

To construct these indexes we use panel data on 14 indicators, for 35 countries and 10 periods, to identify common factors, some of which, as we shall show, will pertain to innovation and infrastructure. We generalize in the panel dimension the approach of common factors that has been proposed a long time ago (see Bartholomew et al. (2009)) and received new attention in recent years in the literature on common features (Anderson, Issler and Vahid, 2006). We then apply these common factors to the explanation of international differences in productivity. The idea behind factor analysis is to summarize various indicators into a limited number of common factors that explain most of the correlations between the individual indicators so as to reduce the dimension of the analysis. Here are a few examples of applications of this procedure. In macroeconomics, Hecq, Palm and Urbain (2006) identify two or three common cyclical features to explain comovements in annual GDP series of 5 Latin American countries over a 50-year period. In the analysing the quality of patents, Lanjouw and Schankerman (2004) estimate by factor analysis a patent quality index common to four quality indicators (claims, citations, family size and technology area). Fagerberg and Srholec (2008) use factor analysis on pooled data for 115 countries, 25 indicators and 2 periods (average values for 1992-1994 and for 2002-2004) to isolate four

types of indicators, which they interpret as capabilities: the development of the innovation system, the quality of governance, the political system and the openness of the economy.

Compared to the previous studies we innovate in two respects. On the one hand, we allow for two kinds of common factors, those in the cross-sectional dimension and those in the time series dimension. It is like replacing the cross-sectional specific and the time series specific errors in the two-way error components model by common factors in the two respective dimensions. On the other hand, instead of estimating first the common factors and inserting them afterwards in a factor-augmented productivity equation, we propose a more robust Bayesian approach based on uninformed priors and Markov Chain Monte Carlo simulation where all equations are estimated simultaneously.

The paper is organized as follows. We first present the factor augmented productivity model and then we explain two ways to estimate this model: the frequentist approach and the Bayesian approach. After presenting the data, we analyze the results, the individual and time factor scores followed by the estimation of the factor-augmented productivity equation.

2 The factor-augmented productivity model

As Bai and Ng (2008) pp.114 say “*the motivation for considering factor analysis is to deal with large number of variables. Use of a small number of factors as conditioning variables is a parsimonious way to capture information in a data rich environment, and there should be efficient gains over (carefully) selecting a handful of predictors*”.

Generally, the factor-augmented regression (FAR) is used to add factors estimated by principal components analysis to a standard equation. Let N be the number of cross-section units (countries) and T be the number of time

series observations (years). A standard specification of a FAR¹ is defined as:

$$\begin{cases} y_{it} &= f(X_{it}, \tilde{f}_t) + u_{it} = X_{it}\beta + \mu_i\tilde{f}_t + u_{it} \\ z_{it,l} &= \gamma_l\tilde{f}_t + e_{it,l}, \quad l = 1, \dots, L, \quad i = 1, \dots, N, \quad t = 1, \dots, T \end{cases} \quad (1)$$

where y_{it} is the dependent variable (*i.e.*, the productivity) for cross-section i at time t , X_{it} is the $(1 \times K)$ vectors of inputs, $\tilde{f}_t (= E[f_t|z_{it,l}])$ are the estimated factor scores and ε_{it} is an error component:

$$u_{it} = \alpha_i + \varepsilon_{it} \text{ with } \alpha_i \sim N(0, \sigma_\alpha^2), \quad \varepsilon_{it} \sim N(0, \sigma_\varepsilon^2) \quad (2)$$

$z_{it,l}$ is the l^{th} observed indicator and these indicators may include R&D, publications, trademark, royalties, ... γ_l is referred to as the factor loadings, f_t is the unobserved common factors (or common shocks). Since f_t is unobservable, we normalize by setting its variance to one: $f_t \sim N(0, 1)$. Each indicator contains an idiosyncratic error $e_{it,l} \sim N(0, \sigma_{e_l}^2)$. The regression model given by (1) can usually encompass many applications of interest. It is simply a regression with generated regressors \tilde{f}_t and $f(X_{it}, \tilde{f}_t)$ is the estimated conditional mean of y_{it} . Generated regressor \tilde{f}_t can be obtained as the fitted values from a first step regression of a multiple-indicator ($z_{it,l}$) related to the latent common factor. As shown in Pagan (1984), sampling variability from the first step estimation is $O_p(1)$ in the second step. Consequently, the standard errors of the second step parameter estimates $(\beta', \mu_i)'$ in (1) must account for the estimation error from the first step. But, Bai and Ng (2008) have shown that no such adjustment is necessary if $\sqrt{T}/N \rightarrow 0$.

¹The literature on common factors for panel data is now huge (see Anderson, Issler and Valid (2006)) but many applications concern the FAR (see (eq. 1)) or the random error model with common factors $f_t : y_{it} = X_{it}\beta + u_{it}$ with $u_{it} = \lambda'_i f_t + \eta_{it}$. For instance and recently, Gonçalves and Perron (2010) propose a bootstrapping FAR in a very specific model: $y_t = \beta'W_t + \alpha'f_t + e_t$ where the unobserved regressors f_t are the common factors in the following panel factor model: $X_{it} = \lambda'_i f_t + \eta_{it}$. Moench et al. (2009) propose dynamic hierarchical factors models to characterize within-block and between-block variations as well as idiosyncratic noise in large dynamic panels. Their model is estimated using a Markov Chain Monte-Carlo algorithm that takes into account the hierarchical structure of the factors. Komujer and Ng (2010) propose an indirect estimation of model with latent error components: $y_{it} = X_{it}\beta + \lambda'_i f_t + \eta_{it}$ with $X_{it} = \lambda'_i g_t + x_{it}$, etc.

2.1 The frequentist approach: a multi-step model

In our case, we introduce both p_N individual common factors $(q_{i1}, \dots, q_{ip_N})$ and a time common factor² (f_t) to express the quality of innovation, following Lanjouw and Schankerman (2004) and Fagerberg and Srholec (2008). So, the factor-augmented regression is now defined as:

$$\begin{cases} y_{it} &= f(X_{it}, \widetilde{q}_{i1}, \dots, \widetilde{q}_{ip_N}, \widetilde{f}_t) + u_{it} = X_{it}\beta + \sum_{j=1}^{p_N} \delta_j \widetilde{q}_{ij} + \mu \widetilde{f}_t + u_{it} \\ \bar{z}_{i,l} &= \sum_{j=1}^{p_N} \lambda_{lj} q_{ij} + e_{i,l}, \quad l = 1, \dots, L_N \text{ with } p_N < L_N \\ \bar{z}_{t,m} &= \gamma_m f_t + e_{t,m}, \quad m = 1, \dots, L_T \end{cases} \quad (3)$$

where $\bar{z}_{i,l}$ are the individuals means $(= \sum_{t=1}^T z_{it,l}/T)$, $\bar{z}_{t,m}$ are the time means $(= \sum_{i=1}^N z_{it,m}/N)$, \widetilde{q}_{ij} ($= E[q_{ij}|\bar{z}_{i,l}]$) (resp. \widetilde{f}_t ($= E[f_t|\bar{z}_{t,m}]$)) are the estimated factor scores for individuals means $\bar{z}_{i,l}$ (resp. for time means $\bar{z}_{t,m}$). λ_{lj} and γ_m are factor loadings and unobservable common factors $((q_{i1}, \dots, q_{ip_N})$ and f_t) are *iid* $N(0, 1)$.

We can use a multi-step estimation method with principal component analysis for the first two steps. In these two steps, generated regressors $(\widetilde{q}_{i1}, \dots, \widetilde{q}_{ip_N})$ and \widetilde{f}_t can be obtained as the fitted values from regressions of multiple-indicators $(\bar{z}_{i,l})$ (resp. $(\bar{z}_{t,m})$) related to the individual latent common factors $(q_{i1}, \dots, q_{ip_N})$ (resp. the time latent common factor f_t). Regression scores will appear as expected values of the factors, given the indicators (see Bartholomew et al. (2009)). The third step uses ML estimator of the one-way error component model.

2.2 The Bayesian approach

Since we have not derived the asymptotic properties of this multi-step approach, estimation may lead to biased and inefficient estimators in the third step and we don't know if the condition $(\sqrt{T}/N \rightarrow 0)$ on (eq. 1) has two equivalents for (eq. 3). One way to avoid these problems is to estimate jointly, in one step, the system (3). This can be done using Bayesian approach (see

²We can generalize the specification with $p_T > 1$ time common factors.

Press and Shigemasu (1997)). Let us re-write the factor-augmented regression in matrix form:

$$\begin{cases} y_{it} &= X_{it}\beta + \underset{(1 \times p_N)(p_N \times 1)}{\delta'} q_i + \mu f_t + \alpha_i + \varepsilon_{it} \\ &= X_{it}\beta + v_{it} \\ \bar{z}_i &= \underset{(L_N \times 1)}{\Lambda} \underset{(L_N \times p_N)(p_N \times 1)}{q_i} + \underset{(L_N \times 1)}{e_i} \\ \bar{z}_t &= \underset{(L_T \times 1)}{\Gamma} \underset{(L_T \times 1)(1 \times 1)}{f_t} + \underset{(L_T \times 1)}{e_t} \end{cases} \quad (4)$$

where $\bar{z}_i = (\bar{z}_{i,1}, \dots, \bar{z}_{i,L_N})'$, $\bar{z}_t = (\bar{z}_{t,1}, \dots, \bar{z}_{t,L_T})'$, Λ (resp. Γ) is a matrix (resp. a vector) of constants called the individual factor loading matrix (resp. the time factor loading vector) and $q_i = (q_{i1}, \dots, q_{ip_N})'$ is the individual factor scores vector for cross-section i . The e_i (resp. the e_t) are assumed to be mutually uncorrelated and multivariate normally distributed as $MN(0, \Psi)$ (resp. as $MN(0, \Phi)$). Ψ and Φ are not assumed to be diagonal. This specification can be viewed as a general factor-augmented two-way error component model with³:

$$v_{it} = \kappa_i + \omega_t + u_{it} = \delta' q_i + \mu f_t + \alpha_i + \varepsilon_{it} \quad (5)$$

In other words, the probability laws $\ell(\cdot)$ of y_{it} , \bar{z}_i and \bar{z}_t are:

$$\begin{cases} \ell(y_{it}|\beta, \delta, \mu, \sigma_\alpha^2, \sigma_\varepsilon^2) &= N(X_{it}\beta, \sigma_y^2) \\ \ell(\bar{z}_i|\Lambda, q_i, \Psi) &= MN(\Lambda q_i, \Psi) \\ \ell(\bar{z}_t|\Gamma, f_t, \Phi) &= MN(\Gamma f_t, \Phi) \end{cases} \quad (6)$$

with $\sigma_y^2 = \delta' \delta + \mu^2 + \sigma_\alpha^2 + \sigma_\varepsilon^2$ or equivalently:

$$\begin{pmatrix} y_{it} \\ \bar{z}_i \\ \bar{z}_t \end{pmatrix} \sim MN \left(\begin{pmatrix} X_{it}\beta \\ \Lambda q_i \\ \Gamma f_t \end{pmatrix}, \begin{pmatrix} \sigma_y^2 & \delta' \Lambda' & \mu \Gamma' \\ \Lambda \delta & \Psi & 0 \\ \Gamma \mu & 0 & \Phi \end{pmatrix} \right) \quad (7)$$

Following Lindley and Smith (1972) (see Bresson and Hsiao (2011), Bresson et al. (2011)), we express model (4) in three stages of hierarchy.

1. The first stage of the hierarchy postulates the joint density function of the data $(y_{it}, \bar{z}_i, \bar{z}_t)$ conditional on $(X_{it}, q_i, f_t, \pi, \Lambda, \Gamma)$ such that:

$$p(y_{it}, \bar{z}_i, \bar{z}_t | X_{it}, q_i, f_t, \pi, \Lambda, \Gamma) \propto p(y_{it} | X_{it}, q_i, f_t, \pi) \cdot p(\bar{z}_i | q_i, \Lambda) p(\bar{z}_t | f_t, \Gamma) \quad (8)$$

where $\pi = (\beta', \delta', \mu)'$.

³We could imagine that $\sigma_\alpha^2 = 0$.

2. The second stage of the hierarchy postulates the prior distributions of $(\pi, \Lambda, \Gamma, \sigma_\alpha^2, \sigma_\varepsilon^2, \Psi, \Phi)$:

$$p(\pi|X_{it}) \sim MN(\bar{\pi}, \Omega_\pi) \quad (9)$$

$$p(\Lambda|\bar{z}_i) \sim MN(\bar{\Lambda}, \Omega_\Lambda) \quad (10)$$

$$p(\Gamma|\bar{z}_t) \sim MN(\bar{\Gamma}, \Omega_\Gamma) \quad (11)$$

$$p(\Psi^{-1}) \sim W_{L_N}((\rho_\Psi R_\Psi)^{-1}, \rho_\Psi) \quad (12)$$

$$p(\Phi^{-1}) \sim W_{L_T}((\rho_\Phi R_\Phi)^{-1}, \rho_\Phi) \quad (13)$$

$$p(\sigma_\alpha^2) \sim IG\left(\frac{\tau_\alpha}{2}, \frac{\eta_\alpha}{2}\right) \quad (14)$$

$$p(\sigma_\varepsilon^2) \sim IG\left(\frac{\tau_\varepsilon}{2}, \frac{\eta_\varepsilon}{2}\right) \quad (15)$$

3. The third stage of the hierarchy postulates the prior distributions of $(\bar{\pi}, \bar{\Lambda}, \bar{\Gamma})$:

$$\bar{\pi} \sim MN(\bar{\bar{\pi}}, \Omega_{\bar{\pi}}), \bar{\Lambda} \sim MN(\bar{\bar{\Lambda}}, \Omega_{\bar{\Lambda}}) \text{ and } \bar{\Gamma} \sim MN(\bar{\bar{\Gamma}}, \Omega_{\bar{\Gamma}}) \quad (16)$$

We have supposed that Ψ^{-1} follows a Wishart distribution (a multivariate generalization of the gamma distribution) with scale matrix $(\rho_\Psi R_\Psi)$ and degrees of freedom ρ_Ψ . We have also supposed that σ_α^2 and σ_ε^2 are independent and follow inverse-gamma distributions. The scale hyperparameter $(\frac{\eta_\alpha}{2}$ or $\frac{\eta_\varepsilon}{2})$ controls the precision of the prior. Small values of $(\frac{\eta_\alpha}{2}$ or $\frac{\eta_\varepsilon}{2})$ correspond to precise priors and the view that σ_α^2 or σ_ε^2 is probably constant over individuals, implying nearly homoscedastic disturbances. Large values

of $(\frac{\eta_\alpha}{2}$ or $\frac{\eta_\varepsilon}{2})$ convey the view that disturbances may be quite variable or heteroscedastic. Generally, in order to implement the Gibbs sampler, we fix values of shape $(\frac{\tau_\alpha}{2}$ or $\frac{\tau_\varepsilon}{2})$ and scale $(\frac{\eta_\alpha}{2}$ or $\frac{\eta_\varepsilon}{2})$ hyperparameters. Let $Z^{(i)'} = (\bar{z}_1, \dots, \bar{z}_N)$, $Z^{(t)'} = (\bar{z}_1, \dots, \bar{z}_T)$, $Q^{(i)'} = (q_1, \dots, q_N)$ and $F^{(t)'} = (f_1, \dots, f_T)$. Combining the priors (9)-(16) with the data $(y_{it}, \bar{z}_i, \bar{z}_t)$, we can obtain the posteriors of $\theta = (\pi, \Lambda, \Gamma, \Psi, \Phi, \sigma_\alpha^2, \sigma_\varepsilon^2)$:

$$\begin{aligned}
p(\theta | y_{it}, \bar{z}_i, \bar{z}_t) \propto & \prod_{i=1}^N \prod_{t=1}^T (2\pi\sigma_y^2)^{-\frac{1}{2}} \left\{ \exp \left[-\frac{1}{2\sigma_y^2} (y_{it} - X_{it}\beta)' (y_{it} - X_{it}\beta) \right] \right\} \\
& \times |\Psi|^{-\frac{N}{2}} \exp \left[-\frac{1}{2} \text{tr} \Psi^{-1} (Z^{(i)} - Q^{(i)}\Lambda')' (Z^{(i)} - Q^{(i)}\Lambda') \right] \\
& \times |\Phi|^{-\frac{T}{2}} \exp \left[-\frac{1}{2} \text{tr} \Phi^{-1} (Z^{(t)} - F^{(t)}\Gamma')' (Z^{(t)} - F^{(t)}\Gamma') \right] \\
& \times |\Omega_\pi|^{-\frac{1}{2}} \exp \left[-\frac{1}{2} (\pi - \bar{\pi})' \Omega_\pi^{-1} (\pi - \bar{\pi}) \right] \\
& \times |\Omega_\Lambda|^{-\frac{1}{2}} \exp \left[-\frac{1}{2} (\Lambda - \bar{\Lambda})' \Omega_\Lambda^{-1} (\Lambda - \bar{\Lambda}) \right] \\
& \times |\Omega_\Gamma|^{-\frac{1}{2}} \exp \left[-\frac{1}{2} (\Gamma - \bar{\Gamma})' \Omega_\Gamma^{-1} (\Gamma - \bar{\Gamma}) \right] \\
& \times (\sigma_\alpha^{-2})^{\frac{\tau_\alpha}{2}+1} \left(\frac{\eta_\alpha}{2} \right)^{\frac{\tau_\alpha}{2}} \exp \left[-\sigma_\alpha^{-2} \frac{\eta_\alpha}{2} \right] \\
& \times (\sigma_\varepsilon^{-2})^{\frac{\tau_\varepsilon}{2}+1} \left(\frac{\eta_\varepsilon}{2} \right)^{\frac{\tau_\varepsilon}{2}} \exp \left[-\sigma_\varepsilon^{-2} \frac{\eta_\varepsilon}{2} \right] \\
& \times |\Psi|^{-\frac{1}{2}(\rho_\Psi - L_N - 1)} \exp \left[-\frac{1}{2} \text{tr} [(\rho_\Psi R_\Psi) \Psi^{-1}] \right] \\
& \times |\Phi|^{-\frac{1}{2}(\rho_\Phi - L_T - 1)} \exp \left[-\frac{1}{2} \text{tr} [(\rho_\Phi R_\Phi) \Phi^{-1}] \right]
\end{aligned} \tag{18}$$

Unfortunately, there is no closed form for the posteriors. The posterior distributions of $\theta = (\pi, \Lambda, \Gamma, \Psi, \Phi, \sigma_\alpha^2, \sigma_\varepsilon^2)$, given the observed data, are very complicated and are not amenable to analytical calculation or to direct Monte Carlo sampling. Hence MCMC is used to approximate the desired posterior

distributions and we use the statistical package WinBUGS (Spiegelhalter, Thomas and Best (2000)).

In principle, all prior distributions are specified to be as noninformative as possible. A multivariate normal distribution, $N(0_K, 10^2 I_K)$ is chosen for the the $(K \times 1)$ vector of hyperparameters $\bar{\pi}$. An inverse-gamma prior $(0.1, 0.1)$ is chosen for the variance parameters σ_α^2 and σ_ε^2 . Selecting a prior for the covariance matrices Ω_Λ and Ω_Γ turned out to be a more interesting and challenging problem. The conjugate prior, inverse Wishart with scale matrix R_Ψ (resp. R_Φ) and degrees of freedom ρ_Ψ (resp. ρ_Φ), is commonly used in practice. The degrees of freedom must satisfy $\rho_\Psi \geq N - L_N$ to yield a proper prior distribution⁴. Ω_Λ^{-1} is assigned Wishart prior with $\rho_\Psi = 23$ degrees of freedom with the prior scale matrix R_Ψ set to $10^{-2} I_{L_N}$. In the same way, Ω_Γ^{-1} is assigned Wishart prior with $\rho_\Phi = 23$ degrees of freedom with the prior scale matrix R_Φ set to $10^{-2} I_{L_T}$. $\bar{\pi}$ is a $(K \times 1)$ zero vector and $\Omega_{\bar{\pi}} = 10^2 I_K$. $\bar{\Lambda}$ and $\bar{\Gamma}$ are initialized as estimated factor loadings coming from the principal component analysis. $\Omega_{\bar{\Lambda}} = 10^{-1} I_{L_N}$ and $\Omega_{\bar{\Gamma}} = 10^{-1} I_{L_T}$. Results from convergence diagnostics indicated that it was sufficient to burn-in the first 5,000 samples and take the subsequent 20,000 samples.

3 The dataset

The data for the indicators that we use to infer the common factors in the cross section and time series dimensions are taken from the World Development Indicators compiled by the World Bank from officially recognized international sources⁵. In our search for useful indicators we are driven by two criteria: first, we expect the common factors to pertain to innovation and infrastructure indicators, and second, we retain variables that are available for a great number of countries and for which there are not too many missing observations over time. In the end we choose 14 indicators. Since we work with averages over countries and over time, we need not have observations for all years for all the variables, but well for a good number of them (corresponding to the dimension L_T). For some variables, we need to reconstruct some of the data by interpolation and extrapolation. Likewise for the choice of the countries and the period of our analysis we are to a large extent conditioned by the availability of data.

⁴We have tried several initial values for the priors but results remain the same.

⁵See <http://data.worldbank.org/data-catalog/world-development-indicators>

We selected 14 indicators from 37 countries over a 10-year period (from 1998 to 2007). The countries are Argentina, Brazil, Canada, Chile, China, Colombia, Costa Rica, Croatia, the Czech Republic, Ecuador, Estonia, Finland, France, Germany, Honduras, Hungary, India, Ireland, Israel, Italy, Japan, Korea, Lithuania, Mexico, the Netherlands, Norway, Poland, Russia, Singapore, the Slovak Republic, Slovenia, Spain, Turkey, Thailand, Great Britain, Panama, Peru, the United States of America, and Uruguay. The indicators are R&D expenditure per capita, publications per capita, trademark per capita, royalties and license fees per capita, arable land per capita, total country area, education spending per capita, electric power consumption per capita, percentage of total roads paved, length of railway route, life expectancy at birth, secure internet servers per capita, internet users per capita and fixed broadband internet subscribers per capita. The first four are technological indicators and the other ones are infrastructure indicators in the broad sense, including measures of health, education, transportation and communication.

In appendix table A1, we list the variables, their measures and sources, the number of constructed observations, and the means of the indicators (in logs) at the individual level and at the yearly level.

4 The results

4.1 The individual and time factor scores

All variables are log-transformed. For the 37 countries over the 1998 – 2007 period, $L_N = 14$ individual means $(\bar{z}_{i,l})$ of indicators are constructed. For the construction of the time means $(\bar{z}_{t,m})$ we only keep the indicators with the largest time variabilities and eliminate from the above list the following indicators: electricity consumption per capita, arable lands per capita, total country area, percentage of roads paved, and length of railway route life.

As usual in factor analysis, the variables are standardized. We use the mean and standard deviation of $(\bar{z}_{i,l})$ for $l = 1, \dots, L_N$ and of $(\bar{z}_{t,m})$ for $m = 1, \dots, L_T$. It implies that a change of a composite variable over individuals (resp. over time) will reflect changes in each country's position relative to other countries (resp. changes in the importance of the underlying indicators over time, relative to other indicators). The principal-component method is used to analyze the correlation matrix. The factor loadings are computed

using the squared multiple correlations as estimates of the communality (the variance shared with other variables).

The sum of all eigenvalues is the total number of variables. Proportion indicates the relative weight of each factor in the total variance. Remember that the number of principal components that we should retain depends on how much information (*i.e.*, unaccounted variance) we are willing to sacrifice, which of course, is a judgemental question. In general and in the case of standardized data, three suggested rules are used:

- the Kaiser criterion suggests to retain those factors with eigenvalues equal or higher than 1.
- the scree plot (plot of eigenvalues against each principal component) and its typical form with an elbow. The number of principal components that need to be retained is given by the elbow.
- The parallel analysis (*i.e.*, a regression equation to estimate the eigenvalues for random data for standardized data inputs (see Allen and Hubbard (1986))). The observed eigenvalues should be higher than the estimated eigenvalues obtained from this regression.

In our case, the first criterion leads to retain three factors (see Figure 1). But the two first factors (resp. the third factor) explain 52.03%, 23.8% (resp. 8.96%) of the total variance. Hence cumulatively the two first factors account for 75.83% of the total variance. Furthermore, the parallel analysis shows that the difference between the third eigenvalue and the estimated one is small (0.06) as compared to the first two ones (5.92 and 2.07). So, we prefer to retain only the first two factors and it will allow us to get a more tractable interpretation of these factors.

As usual in factor analysis, loadings of the 14 indicators on the two retained factors are adjusted through the so-called “rotation” to maximize the differences between them. We use the “varimax normalized” rotation which assumes that the underlying factors are uncorrelated⁶.

Factor loadings are the weights and correlations between each variable and

⁶We can use a more flexible “oblique” rotation if we suppose that there may be a good deal of correlation between the different factors. These are rotations of the axes that preserve the norms of the rows of the loadings but not the angles between the axes or the angles between the rows.

the factor. Remember that the higher the load the more relevant is the corresponding variable in defining the factor’s dimensionality. A negative value indicates an inverse impact on the factor. The factor loadings of variables (R&D, publication, royalties, education, electricity, life expectation and paved roads) with factor 1 are much greater than those with factor 2 (see Table 1 and Figure 2). Indeed, 85.42% $((0.97 + 0.95 + 0.82 + 0.93 + 0.95 + 0.74 + 0.62)/7)$ of the total factor loadings of factor 1 are due to these variables. The Bayesian approach gives similar results.

Table 1 reports the posterior mean, the standard error and the Monte Carlo standard error of the mean (MC error, see Roberts (1996)) of the factor loadings. One way to assess the accuracy of the posterior estimates is by calculating the Monte Carlo error (MC error) for each parameter. This is an estimate of the difference between the mean of the sampled values (which we are using as our estimate of the posterior mean for each parameter) and the true posterior mean. As a rule of thumb, the simulation should be run until the Monte Carlo error for each parameter of interest is less than about 10% of the sample standard error (see Brooks and Gelman (1998)).

The factor loadings of variables trademark, internet servers and fixed broadband with factor 2 are much greater than those with factor 1: their weights are respectively 0.80, 0.81 and 0.84. One can note that total area, rails and, in a lower proportion, arable lands have negative impacts on factor 2: their weights are respectively -0.90 , -0.84 and -0.26 . In other words, this second factor is defined by opposite factor loadings. One could argue that the common factor 1 measures “*technological capabilities*” while the common factor 2 measures “*networks and geographical capabilities*”.

Uniqueness is the variance that is ‘unique’ to the variable and not shared with other variables. It is equal to $1 - \text{communality}$. For example, 90% (resp. 60%, 34%) of the variance in arable lands (resp. in paved roads, and life expectations) is not shared with other variables in the overall factor model. On the contrary, R&D (resp. electricity, rails, internet users and internet servers) has a low variance not accounted for by other variables 5.2% (resp. 8.3%, 8.7%, 8.9% and 9.2%). Notice that the greater ‘uniqueness’, the lower the relevance of the variable in the factor model. The squared multiple correlations (SMC) between each variable and all other variables is a theoretical lower bound for communality, so it is an upper bound for uniqueness. These SMC are high for the major variables.

Table 1 also gives the Kaiser-Meyer-Olkin (KMO) measure of sampling ad-

equacy⁷. The overall KMO is 0.82. One can note 4 groups of variables according to this KMO measure. The first one, whose KMO is greater than 0.9 is composed of education, royalties and internet users. The second one, whose KMO is close to 0.8 is composed of R&D, publications, trademark, electricity, life expectation, internet servers and fixed broadband. The third one, whose KMO is close to 0.7 is composed of roads, rails and area. The last one is only composed of arable lands whose KMO is very small (0.3). Last, Table 1 gives the scoring coefficients which are the weights used for estimating the regression factor scores. One can see that weights associated with R&D (0.16), publication (0.15), electricity (0.15), education (0.14) and royalties (0.12) are relatively important for the technological capabilities. For the networks and geographical capabilities, the scoring coefficients of fixed broadband (0.22), internet servers (0.19) and trademark (0.19), on one side and those of rails (-0.26) and total area (-0.24), on the other side, are the most important for estimating the regression factor scores.

Just as for the individual means, the factor analysis has also been done for the time means. The Kaiser criterion, the scree plot and the parallel analysis suggest to retain only one factor (see Figure 3) which explains 81.7% of the total variance. One could argue that this factor measures common shocks or “*time trends*”. Table 2 shows that all the variables have high positive weights (> 0.94) except for the fixed broadband (-0.47) and correlatively low uniqueness (< 0.05) except for R&D (0.11), trademark (0.53) and fixed broadband (0.78). One can note that the fixed broadband have a negative impact on this factor associated with time trends and, furthermore, we get high squared multiple correlations (SMC) between each variable and all other variables (> 0.98). On the contrary, the overall Kaiser-Meyer-Olkin (KMO) measure is low (0.53) leading to mediocre values except for electricity and broadband. Figure 4 plots factors scores and defines 4 large (or 16 small) quadrants from the lowest to the highest scores leading to clusters of countries depending on their relative positions.

Once these scoring coefficients are obtained, factor scores are computed by regression method (see Bartholomew et al. (2009)). Regression factor scores

⁷This measure takes values between 0 and 1, with small values meaning that overall the variables have too little in common to warrant a factor analysis. Kaiser recommends accepting values greater than 0.5 as acceptable. Values below this should lead either to collect more data or rethinking which variables to include. Furthermore, values between 0.5 and 0.7 are mediocre, values between 0.7 and 0.8 are good, values between 0.8 and 0.9 are great and values above 0.9 are superb.

predict the location of each individual on the factor. These regression scores therefore appear as expected values of the factors, given the indicators. In this sense, they are reasonable predictors of the common factors (see Table 3, Figures 5 and 6 for individual means and Table 4 and Figure 7 for time means).

On Table 3, the estimated factor scores for technological (resp. networks and geographical) capabilities have, of course, zero mean and unit variance: -3.78×10^{-9} and 1.000 (resp. 2.01×10^{-9} and 1.000). The Bayesian approach does not give strictly similar means of scores for Factor 1 and Factor 2. The MC error confirms the accuracy of the posterior estimates. On Figure 5, for technological capabilities, the minimum value is for Honduras and the maximum for United States. We have also drawn the $\pm 0.5\sigma$ and $\pm\sigma$ confidence intervals (shortdash dot and dash lines). These confidence intervals include respectively the 38% and the 68% of the distribution around the mean. The $\pm\sigma$ confidence interval allows us to define 4 groups of country:

- $[-2; -\sigma]$: very small technological capabilities (Honduras, India, Ecuador, Peru, China)
- $]-\sigma; 0]$: small technological capabilities
- $]0; +\sigma]$: high technological capabilities
- $] +\sigma; 2]$: very high technological capabilities (USA, Canada, Norway, Finland, France, Japan, UK and Ireland).

Figure 6 gives the estimated factor score for the networks and geographical capabilities. Due to the negative area effect, the countries with very small geographical and networks capabilities are India, China, the Russian Federation, USA and Brazil. On the contrary, the countries with very high geographical and networks capabilities are Honduras, Panama, Costa Rica, Slovenia, Estonia and Israël. These capabilities express the positive effect of dense networks and the negative effect of countries with large sparsely populated areas. Again, the Bayesian approach does not give strictly similar means of scores for the common factor and the MC error also confirms the accuracy of the posterior estimates. Figure 7 gives the estimated factor scores for time trend. It is a quasi-linear trend and the $\pm\sigma$ confidence interval define 4 sub-periods: $[1998 - 1999]$, $[2000 - 2002]$, $[2003 - 2005]$ and $[2006 - 2007]$.

4.2 The factor-augmented productivity equation

These estimated factor scores, both for individual means and the time means, are used in the productivity equation as generated regressors. Figure 8 plots the factor scores on technological capabilities against GDP per capita (in logs). There is a very close correlation between these two variables. In the lower left quadrant, there are deviations from the regression line which come from a group of large countries like India, China and the Russian Federation and from small countries like Honduras and Ecuador. The correlation is less important between the factor scores on geographical and networks capabilities and the GDP per capita (in logs) (see Figure 9). This will be confirmed by the lower estimated effect in the productivity equation. Figure 10 plots the factor scores on time trends against GDP per capita (in logs) and shows a convex relationship, which reflects a kind of acceleration of time common factors.

Table 5 gives the ML estimation of the error component model and the Bayesian posterior means, standard errors and the MC errors of the productivity equation. We have supposed that the GDP per capita (in logs) depends on three inputs: the gross fixed capital formation (GFCF) per capita (in logs), the school enrollment tertiary (in logs) and the energy use per capita (in logs) augmented with the estimated factors scores. The elasticity of the productivity relatively to the investment (resp. the tertiary, the energy) is 0.745 (resp. 0.112 and -0.087) for the ML estimator and 0.747 (resp. 0.123 and -0.133) for the Bayesian posteriors means. The elasticity of investment is 5.8 times larger than those of the two other inputs. The negative effect of energy on productivity is quite surprising. The more productive the countries are, the less energy users they are. Actually, energy is not a primary input in the value-added measure of output. This needs further examination. Both technological capabilities and geographical and networks capabilities have positive effects on productivity. These are semi-elasticities, *i.e.*, the percentage changes in the GDP per capital from a one unit change in the capabilities. Technological capabilities effects are expected to be 0.314 (resp. 0.343) for the ML estimation (resp. for the Bayesian posterior means). The effects of geographical and networks capabilities are 0.143 (resp. 0.207) for the ML estimation (resp. for the Bayesian posterior means). Last, the time effects are 0.024 (resp. 0.028) for the ML estimation (resp. for the Bayesian posterior means). The variance of the individual effects σ_α^2 (resp. the reminder term σ_ϵ^2) is lower for the Bayesian approach (0.0385 against

0.1722) (resp. 0.007 against 0.084). The log-likelihood of the productivity equation shows the superiority of the Bayesian approach (385.53) over the multi-step ML estimation (321.140).

Figure 11 shows the good adjustment quality of the Bayesian factor-augmented productivity model as compared to the ML estimation procedure. For the frequentist approach (*i.e.*, the multi-step model), the differences between individual means of observed and predicted output per capita are relatively small except for some countries as Norway, UK, Spain or Korea and some relative errors are larger than $\pm 20\%$ (see Figure 12). On the contrary, with the Bayesian approach, we get very good estimates of individual means of GDP per capita since the relative errors are less than $\pm 1\%$ (see Figures 12 and 13). This good adjustment also holds for time means of estimated GDP per capita (see Figures 14 and 15).

5 Conclusion

To evaluate the importance of technology and infrastructure in explaining differences in GDP per capita, we have estimated a factor augmenting GDP per capita equation with 14 technology and infrastructure indicators taken from the World Development Indicators of the World Bank. First, we have done a factor analysis on 37 countries and a 10-year period in which we allow for two kinds of common factors, those based on individual means and those based on yearly means. In a third step, the estimation of the two types of factor loadings and of the productivity equation has been done using ML estimation. But, we have shown that a one-step more robust Bayesian approach, where all equations are estimated simultaneously, leads to better results. The estimates show a sizeable effect of the technological capabilities in explaining GDP per capita.

10-1. Are young French jobseekers of ethnic immigrant origin discriminated against? A controlled experiment in the Paris area

Emmanuel Duguet, Noam Leandri, Yannick L'Horty, Pascale Petit

10-2. Couple's Work Hours, Satisfaction and reconciling Work and family Life

Nathalie Georges, Dominique Méda, Danièle Trancart

10-3. Housing ownership, social housing and unemployment: an econometric analysis of the Paris area

Emmanuel Duguet, Yannick L'Horty, Florent Sari

10-4. Do Public Subsidies Have an Impact on New Firm Survival? An Empirical Study with French Data

Lionel Désiage, Richard Duhautois, Dominique Redor

10-5. The effect of social security payroll tax reductions on employment and wages: an evaluation of the 2003 French reform

Matthieu Bunel, Fabrice Gilles, Yannick L'Horty

10-6. What are Entrepreneurs' Objectives When Starting a New Business?

Lionel Désiage

10-7. Health and Early Retirement: Evidence from French Data for individuals

Thomas Barnay, Karine Briard

10-8. Ageing, chronic conditions and the evolution of future drugs expenditures

Thomas Barnay, Sophie Thiébaud, Bruno Ventelou

10-9. Entrepreneurial motives and performance: Why might better educated entrepreneurs be less successful?

Arnab Bhattacharjee, Jean Bonnet, Nicolas Le Pape, Régis Renault

10-10. Returns to firm-provided training in France: Evidence on mobility and wages

Arnaud Chéron, Bénédicte Rouland, François-Charles Wolff

10-11. Taxation of early retirement windows and delaying retirement: the French experience

Pierre-Jean Messe

10-12. Pre Entry Motives into Entrepreneurship and Post Entry Entrepreneurial Orientation

Jean Bonnet, Nicolas Le Pape

10-13. Hiring Practices, Employment Protection and Temporary Jobs

Anne Bucher

10-14. Young-in Old-out: a new evaluation

Michela Bia, Pierre-Jean Messe, Roberto Leombruni

10-15. On the impact of the TFP growth on the employment rate: does training on-the-job matter?

Eva Moreno-Galbis

10-16. The dynamics of youth labor market integration

Anne Bucher

10-17. Fostering the potential endogenous development of European regions: a spatial dynamic panel data analysis of the Cohesion Policy on regional convergence over the period 1980-2005

Salima Bouayad-Agha, Nadine Turpin, Lionel Védrine

10-18. Cost-saving or Cost-enhancing Mergers: the Impact of the Distribution of Roles in Oligopoly

Nicolas Le Pape, Kai Zhao

10-19. Bankruptcy Risk, Product Market Competition and Horizontal Mergers

Bernard Franck, Nicolas Le Pape

10-20. Endogenous Job Destructions and the Distribution of Wages

Arnaud Chéron, Bénédicte Rouland

10-21. Employment Protection Legislation and Adverse Selection at the Labor Market Entry

Anne Bucher, Sébastien Ménard

11-1. The French "Earned Income Supplement" (RSA) and back-to-work incentives

Denis Anne, Yannick L'Horty

11-2. The effect of place of residence on access to employment: a field experiment on qualified young job applicants in Ile-de-France

Yannick L'Horty, Emmanuel Duguet, Loïc du Parquet, Pascale Petit, Florent Sari

11-3. Why is there a faster return to work near the border?

Jonathan Bougard

11-4. Residential Discrimination and Ethnic Origin: An experimental assessment in the Paris suburbs

Emmanuel Duguet, Yannick L'Horty, Pascale Petit

11-5. The Fateful Triangle : Complementarities between product, process and organisational innovation in the UK and France

Gérard Ballot, Fathi Fakhfakh, Fabrice Galia, and Ammon Salter

The TEPP Institute

The CNRS **Institute for Labor Studies and Public Policies** (the TEPP Institute, FR n°3126 CNRS) gathers together research centres specializing in economics and sociology:

- the **Centre d'Etudes de l'Emploi** (Centre for Employment Studies), **CEE**, Public Administrative Organization, under the leadership of the Ministers of Work and Research
- **l'Equipe de Recherche sur les Marchés, l'Emploi et la Simulation** (Research Team on Markets, Employment and Simulation), **ERMES**, University of Paris II Panthéon-Assas
- the **Centre d'Etudes des Politiques Economiques de l'université d'Evry** (Research Centre focused on the analysis of economic policy and its foundations and implications), **EPEE**, University of Evry Val d'Essonne
- the **Centre Pierre Naville** (Research on Work and Urban Policies), **CPN**, University of Evry Val d'Essonne
- **l'Equipe de Recherche sur l'Utilisation des Données Temporelles en Economie** (Research Team on Use of Time Data in Economics), **ERUDITE**, University of Paris-Est Créteil and University of Paris-Est Marne-la-Vallée
- the **Groupe d'Analyse des Itinéraires et des Niveaux Salariaux** (The Group on Analysis of Wage Levels and Trajectories), **GAINS**, University of the Maine

The TEPP Institute brings together 147 researchers and research professors and 100 PhD students who study changes in work and employment in relation to the choices made by firms and analyse public policies using new evaluation methods.
